

Varroa destructor mite attacks on honeybees threaten wild bumblebees, too, research shows

A mite that spreads a dangerous virus among honeybees also plays an indirect role in infecting wild bumblebees, new [research shows](#).

The Varroa destructor mite lives on honeybees and can spread deformed wing virus (DWV) throughout the hive.

The mite has emerged as a parasite of Western honeybees, after switching from its original host, the Asian honeybee at the beginning of the last century. It has since spread globally through the man-made movement of infested honeybee hives and has turned into a viral vector.

The invasive mite does not live on bumblebees, but University of Exeter scientists have discovered it indirectly affects them by raising infection rates among honeybees, which then spread DWV to nearby bumblebees.

The researchers say their findings highlight the need for beekeepers to treat honeybee colonies affected by mites in order to protect wild bees.

“We compared areas where honeybees had Varroa destructor mites with mite-free areas,” said Dr. Robyn Manley, of the Centre for Ecology and Conservation on the University of Exeter’s Penryn Campus in Cornwall.

“In areas where mites were present—and therefore spreading DWV among honeybees—we found higher rates of the virus among wild bumblebees. Infected honeybees share their environment with bumblebees, feeding on the same flowers and passing on the virus. In effect, the mites turn honeybees into ‘super spreaders’ of DWV.”

A large proportion of honeybees in Britain and many other countries live in hives kept by beekeepers, and Dr. Manley said the study raised an important point for them. “Some beekeepers prefer not to intervene if mites appear in their colonies, but this could be endangering wild bees,” she said.

As parasites on honeybee pupae and adults, Varroa destructor mites spread DWV—which is associated with dramatic colony losses due to increased over-winter mortality.

“There is a global epidemic of DWV, partly driven by the spread of the Varroa destructor mite,” said Professor Wilfert, of the University of Ulm, Germany.

“We know the virus severely affects honeybee colonies. There has been less research into the impact on wild bumblebees, but studies so far suggest it can reduce their lifespan. These results emphasize the important role of beekeepers, regulators and landscape managers in maintaining the health of both managed honeybees and wild bee populations.”

There are various strains of DWV, and the Exeter study supports the view that DWV-B is taking over from DWV-A as the most prevalent strain. DWV-B is known to be more harmful to honeybees, but it is not yet clear if and how the strains affect wild bumblebees differently.
